Approximation Methods 2017-18: implemented models and algorithms

Alex Foglia
6336805
alex.foglia@stud.unifi.it

October 17, 2018

This relation describes the implemented algorithms, in MATLAB language, which solve some of the problems shown during lectures.

All the implemented routines are available at the following remote repository:

https://github.com/alexfoglia1/approximations_methods.git

1 Stirling Numbers

Consider the following:

$$x^n = \prod_{i=1}^n x$$

As the standard definition of numbers power in the continuous domain ($x \in \mathbb{R}$).

In the discrete domain, it is possible to define a discrete counterpart of number powers: pseudo powers.

Let $x, n \in \mathbb{N}$, we define x pseudo-power n as:

$$x^{(n)} = x(x-1)(x-2)\dots(x-n+1) = \frac{x!}{(x-n)!}$$

We can define number powers in terms of pseudo powers, in the way it follows:

$$x^n = \sum_{i=1}^n S_i^n x^{(i)}$$

Where the S_i^n are called *Stirling Numbers* (of second specie).

S_i^n are defined as:

$$\begin{aligned} S_n^n &= S_1^n = 0 \\ S_i^{n+1} &= S_{i-1}^n + i S_i^n \quad i = 2, \dots, n \end{aligned}$$

This recursive definition of Stirling Numbers makes it easy to implement a MATLAB function which receives n, k as input parameters and returns S_k^n .

```
1 function [s] = getStirling(n,k)
2     if (k > n)
3         s=0;
4     elseif (k == 1 || n == k)
5         s=1;
6     elseif (k == 0 && n >= 1)
7         s=0;
8     else
9         s = k * getStirling(n-1, k)
10            + getStirling(n-1, k-1);
11     end
12 end
```

Listing 1: Stirling Numbers MATLAB function

Consider now the following function:

```
1 function [S] = stirling(n)
2     S=zeros(n);
3     for i=1:n
4         for j=1:i
5             S(i,j) = getStirling(i,j);
6         end
7     end
8 end
```

Listing 2: First n rows of Stirling Numbers

Given n , the function `stirling(n)` returns a matrix of size $n \times n$ containing the first n rows of Stirling Numbers.

When executing it, we obtain:

```
>> A = stirling(7)

A =
```

1	0	0	0	0	0	0

Figure 1: First 7 rows of second specie Stirling Numbers

2 Fibonacci Numbers: the fatal bit problem

Consider the following finite difference equation:

$$y_{n+2} = y_{n+1} + y_n \quad n \geq 0 \quad (*)$$

Choosing $y_0 = y_1 = 1$ as the initial conditions, the expression evaluates to:

$$1, 1, 2, 3, 5, 8, 13, 21, 34, \dots$$

Which is known as the Fibonacci succession of numbers.

In order to get a closed form which explicitly define the n -th element of the succession, we must solve the following difference equation:

$$\sum_{i=0}^2 p_i y_{n+i} = 0 \quad (**)$$

Where $p_0 = 1$, $p_1 = -1$ and $p_2 = -1$. Due to the fact that the $(**)$ is an *homogeneous* difference equation with constant coefficients, it is possible to explicit calculate an enclosed form for the n -th term of the succession.

In a numerical analysis environment, such as MATLAB, it is possible to avoid solve $(**)$, but we may face to the *fatal bit problem*.

Consider the following MATLAB functions which calculates the terms of the succession defined by $(*)$, given y_1 and y_2 as the initial conditions.

```
1 function [yn] = fatalbit (len)
2   yn = zeros(1,len);
3   yn(1)=1;
4   yn(2)=(1-sqrt(5))/2;
5   for i=3:len
6       yn(i)=yn(i-1)+yn(i-2);
7   end
8 end
```

Listing 3: Fibonacci / Fatal Bit function in 64 bit precision

Consider to set the following initial conditions:

$$y_1 = 1$$
$$y_2 = \frac{1 - \sqrt{5}}{2}$$

Executing the following instructions:

```
1 yn = fatalbit(70);
2 semilogy(abs(yn),'.');
```

Listing 4: Plot of Fatal Bit

It is possible to see how succession values starts to diverge for $n = 38$. This is due to the 64 bit double precision, in fact, in 32 bit precision the divergence starts for $n = 17$.

Figure 2: Effects of rounding in 64 bit precision

We can verify the divergence in 32 bit precision, modifying the *fatalbit* function in this way:

```

1 function [yn] = fatalbit (len)
2   yn = zeros(1,len);
3   yn(1)=1;
4   yn(2)=single((1-sqrt(5))/2);
5   for i=3:len
6     yn(i)=yn(i-1)+yn(i-2);
7   end
8 end

```

Listing 5: Fibonacci / Fatal Bit function in 32 bit precision

Re-executing the previous seen script, we obtain the plot shown in figure 3.

Figure 3: Effects of rounding in 32 bit precision

3 Mortgage repayment plan model

Suppose we want to contract a mortgage for a capital C , to repay in N installments at a rate i , which we assume it is constant.

We want to estimate the amount of a single installment r :

Let y_n be the residual debt after the n -th payment. We have:

$$y_n = (1 + i)y_{n-1} - r, \quad y_0 = C, y_N = 0 \quad (1)$$

In other words, the residual debt at time n is the residual debt at time $n - 1$ plus accrued interests minus the installment amount.

homogeneous equation associated to (1) is:

$$y_n - (1 + i)y_{n-1} = 0$$

Which characteristic polynome is:

$$z^2 - (i + 1)z$$

And it has roots:

$$z_1 = 0, z_2 = (1 + i)$$

Hence the general solution of the homogenous equation is:

$$y_n = \alpha(1 + i)^n$$

Let us look for a particular solution for the non-homogeneous problem. In this case, we can find a constant solution for the (1):

$$\bar{y} = \frac{r}{i}$$

Hence the general solution for the (1) is:

$$y_n = \alpha(i + 1)^n + \frac{r}{i}$$

Where α is obtained by imposing initial condition that $y_0 = C$. The final solution for the (1) is the following:

$$y_n = (C - \frac{r}{i})(i + 1)^n + \frac{r}{i} \quad (2)$$

We can write a MATLAB function which calculates the residual debt at time N as follows:

```
1 function [yn] = loan(C,r,i,N)
2   yn=zeros(1,N);
3   yn(1)=C;
4   for j=2:N
5       yn(j)=(1+i)*yn(j-1) - r;
6   end
7 end
```

Listing 6: Mortgage repayment function

It is possible to execute the following script:

```

1 C = 10000;
2 interest=0.05;
3 N=100;
4 hold all;
5 for i=1:5
6 ratei=loan(C,460+(i-1)*20,interest,N);
7 plot(ratei,'DisplayName',[ 'installment amount = ' num2str(460+(i-1)*20) ]);
8 end
9 legend(gca,'show','Location','northwest');

```

Listing 7: Loan repayment plot script with different installment amount

Obtaining the plot shown in figure 4.

We note that if interest is the 5% and installment amount is too low, the debt growth exponentially.

Figure 4: Residual debt with different installments amounts

The debt remains constant if the installment covers only interests (in this case, 500), and it reaches zero if and only if the installment amount is greater to 500.

This behavior is compliant to the (2), in fact, if $\frac{r}{i} < C$ the succession diverges.

Suppose we want to contract a mortgage for a capital of $C = 140000$, with an interest of $i = 0.05 = 5\%$, single installment import defined as $r = C \frac{i}{1-(1+i)^{-N}}$, repayable in $N = 10$ installments.

It is possible to use the following script in order to obtain a table where:

- First column is the residual debt at installments i
- Second column is the interest quote at installments i
- Third column is the capital quote at installments i

```

1 function [resDebt,intQuote,capQuote] = loantable(C,interest ,singleimport ,n)
2     resDebt = loan(C,singleimport ,interest ,n);
3     intQuote = zeros(1,n+1);
4     intQuote(1) = 0;
5     intQuote(2) = C*interest ;
6     for i = 3:n+1
7         intQuote(i)=resDebt(i-1)*interest ;
8     end
9     capQuote = zeros(1,n+1);
10    capQuote(1) = 0;
11    for i = 2:n+1
12        capQuote(i) = singleimport-intQuote(i);
13    end
14 end
15
16 Capital = 140000; %vary for other examples
17 Interest = 0.05;
18 N = 10;
19 Import = Capital*(Interest)/(1-(1+Interest)^-N);
20 [resDebt,intQuote,capQuote] = loantable(Capital,Interest ,Import ,N);
21 table = zeros(N+1,3);
22 for j=1:N+1
23     if j<=N
24         table(j,1)=resDebt(j);
25     end
26     table(j,2)=intQuote(j);
27     table(j,3)=capQuote(j);
28 end

```

Listing 8: Mortgage repayment plan table

Executing this script, we obtain the following matrix:

```

table =

    1.0e+05 *

    1.4000         0         0
    1.2887    0.0700    0.1113
    1.1718    0.0644    0.1169
    1.0491    0.0586    0.1227

9	17270	860	16450
10	0	0	17270

4 Coweb Model

The coweb model describes the evolution of the market price related to an asset.
Let:

- p_n be the unitary price of an asset at time n ;
- p_0 be the initial price;
- S_n be the asset units supplied at time n ;
- D_n be the asset units demanded at time n .

We state that demand and supply are functions of the price. In fact:

$$S_n = g(p_{n-1}) \quad (1)$$

For sake of simplicity we assume g as follows:

$$g = b(p_{n-1}) + s_0 \quad (2)$$

Were $b, s_0 > 0$ represent respectively the response in productivity in base to the latest price, and the supply with a null price.

This function describes the tendence to increase productivity when price grows up, and decrease otherwise. We can substitute the (2) in the (1) obtaining:

$$S_n = b(p_{n-1}) + s_0$$

As concerns demand, we assume the following model:

$$D_n = -a(p_n) + d_0$$

Reasonably, it will be:

$$d_0 \gg s_0 > 0$$

We obtain price dinamicity by imposing:

$$\begin{aligned} S_n &= D_n \forall n \\ \Downarrow \\ b(p_{n-1}) + s_0 &= -a(p_n) + d_0 \\ \Downarrow \\ a(p_n) + b(p_{n-1}) &= d_0 - s_0 \quad (3) \end{aligned}$$

Homogeneous equation associated to the (3) has the following characteristic polynome:

$$az^2 + bz \quad (4)$$

(4) has the following roots:

$$az^2 + bz = 0 \Rightarrow z(az + b) = 0 \Rightarrow z_1 = 0, \quad z_2 = -\frac{b}{a}$$

We note that exists a price \bar{p} , greater to 0 for hypotesis.

$$\bar{p} = \frac{d_0 - s_0}{a + b} > 0$$

\bar{p} is a particular solution for (3) so we can write the general solution:

$$p_n = \bar{p} + \left(-\frac{b}{a}\right)^n (p_0 - \bar{p})$$

We can implement the following MATLAB function that explicitly calculates terms of the p_n S_n D_n successions, given a, b, p_0, s_0, d_0 as parameters:

```

1 function [pn,sn,dn,sfun,dfun] = coweb(d0,a,s0,b,p0,nmax)
2   pn = zeros(1,nmax);
3   sn = zeros(1,nmax);
4   dn = zeros(1,nmax);
5   sfun = @(x) b*x+s0;
6   dfun = @(x) -a*x+d0;
7   diff = (d0-s0);
8   pn(1)= p0;
9   sn(1)= s0;
10  dn(1)= -a*p0+d0;
11  for i = 2:nmax
12    pn(i) = diff -b*pn(i-1)/a;
13    sn(i) = sfun(pn(i-1));
14    dn(i) = dfun(pn(i));
15  end
16 end

```

Listing 9: Matlab Coweb Model

Note that $nmax$ is the maximum time steps we want to calculate.

We can now execute these three scripts and observe how the model behavior is sensible to parameter variations:

```

1 [pnStable,snStable,dnStable,sfun,dfun] = coweb(100,0.15,10,0.10,400,10);
2 plot(pnStable);
3 hold on;
4 title('Stable Coweb');
5 plot(snStable);
6 plot(dnStable);

```

Listing 10: Stable Coweb Model

```

1 [pnUnstable,snUnstable,dnUnstable,sfun,dfun] = coweb(100,0.05,10,0.05, 950,10);
2 plot(pnUnstable);
3 hold on;
4 title('Unstable Coweb');
5 plot(snStable);
6 plot(dnStable);

```

Listing 11: Unstable Coweb Model

```

1 [pnDivergent,snDivergent,dnDivergent,sfun,dfun] = coweb(100,0.09,50,0.1, 300,10);
2 plot(pnDivergent);
3 hold on;
4 title('Divergent Coweb');
5 plot(snDivergent);
6 plot(dnDivergent);

```

Listing 12: Divergent Coweb Model

In the following figures, blue lines represent the p_n succession, yellow line represent the d_n succession, and brown lines represent the s_n succession.

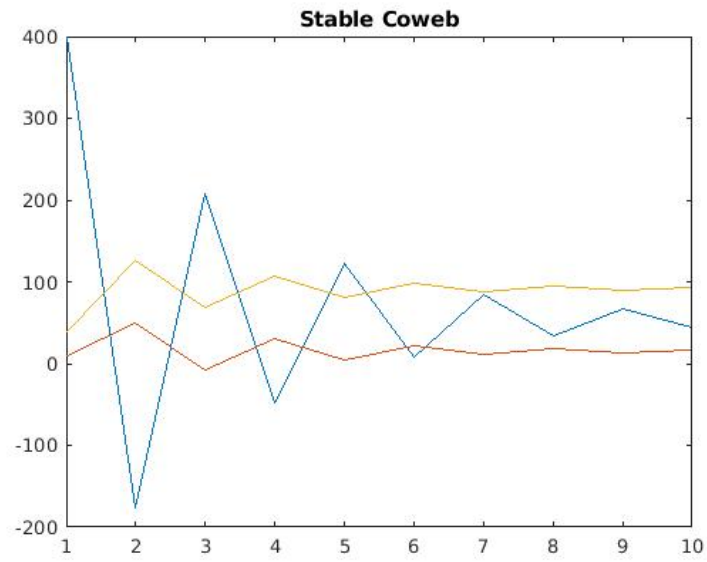

Figure 6: Plot of Stable Coweb successions

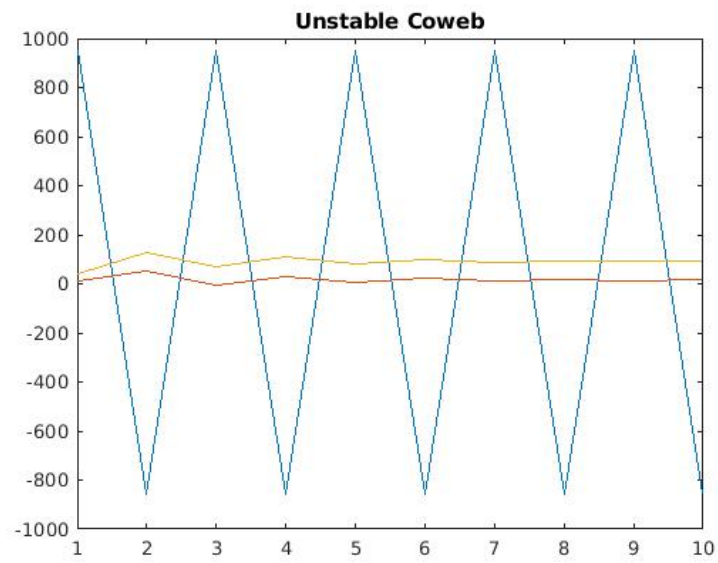

Figure 7: Plot of Unstable Coweb successions

Figure 8: Plot of Divergent Coweb successions

Figure 9: Supply and Demand in the stable case

5 Model of a national economy

This model describes dinamicity of the Gross Domestic Product of a nation. Let:

- Y_n be the GDP
- I_n be the private investments
- G_n be the governative expense
- C_n be the final consume

According to J.M.-Keynes theory, we have:

$$Y_n = I_n + G_n + C_n \quad (1)$$

Suppose it is:

$$C_n = \alpha Y_{n-1} \quad (2)$$

With $0 < \alpha < 1$. Suppose also that investments are proportional to consume increasings:

$$I_n = \rho(C_n - C_{n-1}), \quad \rho > 0 \quad (3)$$

By substituting (3) and (2) in the (1) we obtain:

$$G_n = Y_n - \alpha(\rho + 1)Y_{n-1} + \alpha\rho Y_{n-2} \quad (4)$$

The constant solution is:

$$\bar{Y} = \frac{G}{1 - \alpha}$$

And the characteristic polynome associated to the (4) is:

$$p(z) = z^2 - \alpha(\rho + 1)z + \alpha\rho$$

If we want that solution is asymptotically stable, $p(z)$ must be a Schur's polynome. For this purpose, it is enough that $\rho < \alpha^{-1}$.

1. If α, ρ are both close to 0 there is no economic growth, but the system is stable.
2. If $\alpha > 1$ the system is unstable.
3. If $\alpha \approx 1, \rho < \alpha^{-1}$ the system is stable and the economy stabilizes quickly to an high equilibrium point. This seems to be an optimal condition.
4. If $\alpha \approx 1, \rho \approx 1$ the system is in a stability limit and we have wide oscillations.
5. if $\alpha\rho > 1$ the system loses its stability.

We can implement a MATLAB functions which iteratively calculates the terms of Y_n, I_n, C_n because their definitions comes explicitly from the model.

```

1 function [Y,C,I] = samuelson(alpha,rho,g,y0,y1,nmax)
2     Y=zeros(1,nmax);
3     Y(1)=y0;
4     Y(2)=y1;
5     C=zeros(1,nmax);
6     C(1)=alpha*y0;
7     C(2)=C(1);
8     I = zeros(1,nmax);
9     I(1)=0;
10    I(2)=rho*(C(2)-C(1));
11    for i=3:nmax
12        C(i)=alpha*Y(i-1);
13        I(i)=rho*(C(i)-C(i-1));
14        Y(i)=C(i)+I(i)+g;
15    end
16 end

```

Listing 13: Samuelson Model

Observe now how Y (GDP) varies when varying α, ρ in the first 3 cases

1. α, ρ close to 0:

```
1 [Y,C,I]=samuelson(0.6,0.6,30,100,100,50);  
2 plot(Y);
```

Listing 14: GDP first case plot

Figure 10: GDP values in case 1

2. $\alpha > 1$:

```
1 [Y,C,I]=samuelson(1.5,0.6,30,100,100,50);  
2 plot(Y);
```

Listing 15: GDP second case plot

Figure 11: GDP values in case 2

3. $\alpha \approx 1, \rho < \alpha^{-1}$:

```
1 [Y,C,I]=samuelson(0.999,0.001,30,100,100,50);  
2 plot(Y);
```

Listing 16: GDP third case plot

Figure 12: GDP values in case 3

6 Linear Multistep Methods

6.1 The problem

Consider the following problem:

$$\begin{cases} \dot{y} = f(t, y) \\ y(t_0) = y_0 \end{cases} \quad (*)$$

This problem is known as the *cauchy problem* and it may be solved both in analytic way and numerical.

Since we are interested in numerical methods, our aim is to approximate function $y(t)$ knowing only its derivative $\dot{y} = f(t, y)$ and an initial condition $y(t_0) = y_0$.

Linear Multistep Methods are numerical methods which, fixed an interval $[a, b] \in D(y(t))$ and a number N of times we intend to divide such interval, solve the continuous problem shown in (*) by defining a discrete domain t_i and approximating y values in that discrete domain.

t_i is defined as follows:

$$t_i = a + ih$$

Where:

$$\begin{aligned} i &= 0, \dots, N-1 \\ h &= \frac{b-a}{N} \end{aligned}$$

For example:

$$\begin{aligned} a &= 1, \quad b = 2, \quad N = 5 \\ h &= \frac{2-1}{5} = \frac{1}{5} = 0.25 \\ t_0 &= a + 0h = a = 1.00 \\ t_1 &= a + 1h = 1 + 0.25 = 1.25 \\ t_2 &= a + 2h = 1 + 2 * 0.25 = 1.50 \\ t_3 &= a + 3h = 1 + 3 * 0.25 = 1.75 \\ t_4 &= a + 4h = 1 + 4 * 0.25 = 2.00 = b \end{aligned}$$

Hence:

$$\{t_i\} = \{1.00, 1.25, 1.50, 1.75, 2.00\}$$

We call such t_i a *uniform mesh* with *integration step* $h = 0.25$.

Let y_i be the approximation of the unknown $y(i)$ and remembering that $\dot{y} = f(t, y)$, we define:

$$f_i \equiv f(t_i, y_i)$$

Linear Multistep Methods, more formally, solve discrete problems in the form:

$$\sum_{i=0}^k \alpha_i y_{n+1} = h \sum_{i=0}^k \beta_i f_{n+1} \quad n = 0, \dots, N-k \quad (*)$$

Where $\{\alpha_i\}, \{\beta_i\}$ and k define the particular *k-step linear multistep formula (LMF)*.

It is important to distinguish between k and N , in fact, the first is an intrinsic characteristic of a particular LMF method, and the latter, indeed, is a characteristic of the problem we need to

solve. N is the number of sub-intervals we intend to divide the interval $[a, b]$, and it defines its relative *integration step* $h = \frac{b-a}{N}$. The greater is N , the smaller is h and the more accurate is the approximation with respect to the real function $y(t)$. Integration step and inherent method's step are two completely different concepts.

In conclusion, we define that a particular LMF method is completely identified by its ρ, σ polynomials, where:

$$\rho(z) = \sum_{i=0}^k \alpha_i z^i$$

$$\sigma(z) = \sum_{i=0}^k \beta_i z^i$$

With these definitions, we can write the (*) problem in a more compact notation:

$$\rho(E)y_n - h\sigma(E)f_n = 0 \quad n = 0, \dots, N - k$$

6.2 An implicit implementation

Linear Multistep Methods are distinguished in implicit and explicit. Indeed, if $\beta_k = 0$ we lose the dependence between y_{k+1} and f_{k+1} , which explicitly contains it. We call this case an explicit method, otherwise if it were $\beta_k \neq 0$ then we will not lose this dependence and we would talk about an implicit method.

Here it follows an implementation of an implicit method that, received as parameters the α_i, β_i, y_0 as the initial condition, the integration interval and the known function $f(t, y)$ of which we want to approximate the primitive, returns an approximation of the function $y(t)$ on the desired mesh.

```

1 function [y,t] = linear_multistep(f,t0,y0,h,tf,ai,bi)
2     [n,m] = size(ai);
3     [s,t] = size(bi);
4     if m~=1 || t~=1
5         error('alpha_i and beta_i must be column vectors');
6     elseif n~=s
7         error('alpha_i and beta_i must be equally length');
8     elseif tf<=t0(1)
9         error('tf is greater than t0(1)');
10    end
11    s1 = s-1;
12    n = ceil((tf-t0(1))/h);
13    t = linspace(t0(1),t0(1)+h*n,n+1)';
14    y = zeros(n+1,1);
15    fy = zeros(s1,1);
16    F0 = numjacobian(f,t0,y0);
17    fy(1:s1)=F0;
18    M = inv(eye(s1) - h*(bi(1:s1)'*F0));
19    y(1:s1)=y0(1:s1);
20    k=0;
21    while k < n-s1
22        G = @(x) ai(s)*x + (ai(1:s1)'*y(k+1:s1+k)) - ...
23            h*(bi(1:s1)'*fy(1:s1)) - h*bi(s)*f(t(s+k),x);
24        y(s+k:s+k+s1-1) = one_step(y(s+k:s+k+s1-1),G,M);
25        fy(1:s1-1)=fy(2:s1);
26        fy(s1)=f(t(s+k),y(s+k));
27        k = k+1;
28    end
29 end
30

```

```

31 function [f0] = numjacobian( fun, t0, y0 )
32 %
33 % NUMERICAL JACOBIAN (slightly adapted from the code BiM/BiMD).
34 % 2015.02.12
35 %
36 m = length(y0);
37 Jf = zeros(m);
38 f0 = reshape( feval( fun, t0, y0 ), m, 1 );
39 dd = eps^(1/3);
40 for i = 1:m
41     ysafe = y0(i);
42     delt = sqrt( eps*max(dd,abs(ysafe)) );
43     y0(i) = ysafe +delt;
44     f1 = feval( fun, t0, y0 );
45     Jf(:,i) = ( f1(:) -f0 )/delt;
46     y0(i) = ysafe;
47 end
48 if nargin>1, f0 = f0.'; end
49 return
50 end
51
52
53 function [y] = one_step(yn,G,M,tol,maxit)
54 if nargin == 3
55     tol = 1.e-5;
56     maxit = 1000;
57 elseif nargin == 4
58     maxit = 1000;
59 end
60 y = yn;
61 scal = norm(y)+1;
62 Delta = -M*G(y);
63 it = 0;
64 while norm(Delta)/scal > tol && it < maxit
65     Delta = -M*G(y);
66     y = y + Delta;
67     it = it+1;
68 end
69 if it == maxit
70     warning('Reached max iteration\n');
71 end
72 end

```

Listing 17: Implicit LMF solver

Consider the following problem:

$$\begin{cases} \dot{y} = 10y - 2y^2 \\ y(0) = 1 \end{cases}$$

The exact solution will be

$$y(t) = \frac{5}{1 + 4e^{-10t}}$$

Note that:

$$\lim_{t \rightarrow +\infty} y(t) = 5$$

If we execute the following script, we obtain two different approximations of the function given by the midpoint and the implicit euler methods, defined by the following coefficients.

Implicit Euler:

$$\alpha_i = \{-1, 1\}$$

$$\beta_i = \{0, 1\}$$

Midpoint:

$$\alpha_i = \{-1, 0, 1\}$$

$$\beta_i = \{0, 2, 0\}$$

```

1 fun = @(t,y) 10*y-2*y.^2;
2 FUN = @(t) 5/(1+4*exp(-10*t));
3 t0 = 0;
4 tf = 2.5;
5 h = 0.01;
6 N = length(intval);
7 real_values=zeros(1,length(intval));
8 y0 = 1;
9 euler_ai = [-1;1];
10 euler_bi = [1;0];
11 midpoint_ai = [-1;0;1];
12 midpoint_bi = [0;2;0];
13 [euler,ti]=linear_multistep(fun,t0,y0,h,tf,euler_ai,euler_bi);
14 for i=1:length(ti)
15     real_values(i)=FUN(ti(i));
16 end
17 [midpoint,ti]=linear_multistep(fun,[ti(1),ti(2)],...
18 [real_values(1),real_values(2)],h,tf,midpoint_ai,midpoint_bi);
19 hold on;
20 plot(ti,euler,'DisplayName','Euler');
21 grid on;
22 plot(ti,midpoint,'DisplayName','Midpoint');
23 plot(ti,real_values,'DisplayName','Exact solution');
24 legend(gca,'show','Location','best');
```

Listing 18: Compare LMF

We note in figures 13 and 14 that the midpoint formula makes spurious oscillations that becomes more frequent as the step h decreases.

Executing the following script, we can see the error committed by the implicit euler method (figures 15 and 16).

```

1 comparelmf;
2 close all;
3 error_euler = abs(real_values'-euler);
4 plot(error_euler,'DisplayName','Euler Error');
5 hold on;
6 grid on;
7 legend(gca,'show','Location','best');

```

Figure 15: Implicit euler error with step $h = 0.01$

Figure 16: Implicit euler error with step $h = 0.005$

6.3 LMF vs Runge Kutta methods

First we define the *local truncation error* τ_{n+k} as:

$$\tau_{n+k} = \sum_{i=0}^k \alpha_i y(t_{n+i}) - h \sum_{i=0}^k \beta_i \hat{f}_{n+i} \quad n = 0, \dots, N-k$$

Where, once assigned $y(t_n)$ as the exact solution of $y(t)$ evaluated on mesh nodes $\{y(t_n)\}$:

$$\hat{f}_n = f(t_n, y(t_n))$$

We state that a LMF method has *order* p if and only if:

$$\tau_{n+k} = O(h^{p+1})$$

The order of a LMF method gives useful informations about the error affecting the approximation of the integrand function. The bigger is the order, the smaller is the error.

LMF methods ((ρ, σ) methods) are characterized by an important limit on their order: the *Dahlquist barriers*. *Runge Kutta* methods (from here on, RK methods) are iterative methods designed to overcome the *Dahlquist barriers*.

RK methods are the ones used by MATLAB in its built-in functions `ode45` and `ode23`.

RK methods require more than one function evaluation of the integrand function $f(t, y)$ in each interval $[t_n, t_{n+1}] \in \{t_i\}$ (remember that $\{t_i\}$ is our mesh of integration).

In its most general form, a RK method can be written as:

$$y_{n+1} = y_n + h \sum_{i=1}^s b_i K_i$$

Where:

$$K_i = f(t_n + c_i h, y_n + h \sum_{j=1}^s a_{ij} K_j), \quad i = 1, \dots, s$$

and s is the number of *stages* of the RK method, and coefficients $\{a_{ij}\}$, $\{b_i\}$, $\{c_i\}$ completely characterize a RK method, likewise α_i and β_i in LMF methods, and they are stored in a particular matrix called *Butcher's array*:

$\{c_i\}$	$\{a_{ij}\}$
	$\{b_i\}$

One of the most known RK method is the following:

$$y_{n+1} = y_n + \frac{h}{6}(K_1 + 2K_2 + 2K_3 + K_4) \quad (*)$$

Where

$$\begin{aligned} K_1 &= f_n \\ K_2 &= f(t_n + \frac{h}{2}, y_n + \frac{h}{2} K_1) \\ K_3 &= f(t_n + \frac{h}{2}, y_n + \frac{h}{2} K_2) \\ K_4 &= f(t_{n+1}, y_n + h K_3) \end{aligned}$$

This method is derived by applying Simpson's quadrature formula to integrate f between mesh nodes. Consider the following MATLAB function, which perform approximation using the RK method (*):

```

1 function [yn] = explrungekutta(y0,intval,f)
2   N = length(intval);
3   h = intval(2)-intval(1);
4   yn = zeros(1,N);
5   yn(1) = y0;
6   for i=1:N-1
7     Y1 = f(intval(i),yn(i));
8     Y2 = f(h/2+intval(i),yn(i)+h/2*Y1);
9     Y3 = f(h/2+intval(i),yn(i)+h/2*Y2);
10    Y4 = f(intval(i)+h,yn(i)+h*Y3);
11    yn(i+1) = yn(i) + (h/6)*(Y1+2*Y2+2*Y3+Y4);
12  end
13 end

```

Listing 20: Explicit RK implementation

Let us examine the behavior of this RK method in the case shown before:

$$\begin{cases} \dot{y} = 10y - 2y^2 \\ y(0) = 1 \end{cases}$$

$$y(t) = \frac{5}{1 + 4e^{-10t}} \quad \lim_{t \rightarrow +\infty} y(t) = 5$$

Recap that the mesh is:

$$\{t_i\} \in [0, 2.5]$$

$$h = 0.001$$

Executing the following script:

```

1 %rk.m:
2 comparelrf; %inherit y0, fun, ti and real_values
3 close;
4 rk = explrungekutta(y0,ti,fun);
5 hold on;
6 plot(ti,real_values,'DisplayName','Exact Solution');
7 plot(ti,rk,'DisplayName','Runge Kutta');
8 legend(gca,'show','Location','southeast');

```

Listing 21: Runge Kutta approximation plot (rk.m)

We obtain the plot shown in figure 17.

The error committed by the implemented RK method, however, is not always 0. Consider the following script:

```

1 rk;
2 close;
3 er = abs(rk-real_values);
4 hold on;
5 l_in=1;
6 r_in=2500;
7 plot(intval(l_in:r_in),er(l_in:r_in),'DisplayName','Runge Kutta Error');
8 legend(gca,'show','Location','northwest');

```

Listing 22: Plot of RK error

Executing it, we obtain the result shown in figure 18.

Figure 17: The approximation performed by the shown RK method overlaps with the exact solution

Figure 18: Error of the implemented RK method

We note that the implemented RK method commits its maximum error approximately at $t_i \approx 0.45$, and this error results $\approx 3 * 10^{-11}$. However, after a settling period in which the error is however substantially negligible, we note that for $t_i > \approx 1$ the error becomes null.

In conclusion, we state that RK methods are characterized by a greater computational complexity with respect to LMF methods since they perform sN function evaluations, where s is the method's number of stages and N is the number of mesh nodes, but they are:

1. More precise, since they overcome the first Dahlquist barrier;
2. More stable, since they overcome the second Dahlquist barrier.

6.4 Linear Multistep Methods: The Boundary Locus

A particular Linear Multistep Method is identified by its ρ, σ polynomes.

Considering a (ρ, σ) method, we define $D = \{q \in \mathbb{C} : \pi(z, q) \in S\}$ where S is the set of Schur's polynomes, and

$$\pi(z, q) = \rho(z) - q\sigma(z)$$

is the stability polynome associated to the test equation, as the absolute stability region of the considered (ρ, σ) method.

In general, determining the stability region for a LMF method using Schur's criteria could result difficult, so we can study the border of this region: the boundary locus.

The boundary locus is defined as follows:

$$\Gamma = \left\{ q(\theta) = \frac{\rho(e^{i\theta})}{\sigma(e^{i\theta})} : 0 \leq \theta \leq 2\pi \right\}$$

Given the following MATLAB functions, which calculcates (ρ, σ) polynomes of LMF methods:

- BDF
- Adams-Moulton
- Adams-Bashfort

```

1 function [ro,sigma] = lmf( tipo , k )
2 %
3 % [ro,sigma] = lmf( tipo , k )      Calcola i polinomi ro e sigma del metodo
4 %                                  lmf a k passi specificato dal tipo:
5 %
6 %                                  0 : BDF
7 %                                  1 : Adams–Moulton
8 %                                  2 : Adams–Bashforth
9 %
10 if tipo==0 % BDF
11     sigma = [1 zeros(1,k)];
12     b     = [0:k].*[k.^[0:k]]/k;
13     ro     = vsolve(k:-1:0,b);
14 elseif tipo==1 % Adams–Moulton
15     ro     = [1 -1 zeros(1,k-1)];
16     j      = [1:k+1];
17     b      = (k.^j-(k-1).^j)./j;
18     sigma = vsolve( k:-1:0, b );
19 elseif tipo==2 % Adams–Bashforth
20     ro     = [1 -1 zeros(1,k-1)];
21     j      = [1:k];
22     b      = (k.^j-(k-1).^j)./j;
23     sigma = [0 vsolve( k-1:-1:0, b )];
24 else
25     disp(' tipo invalido!'), disp(' '),
26     help lmf, ro=[]; sigma=[];
27 end
28 return
29
30 function f = vsolve( x, b )
31 %
32 %     f = vsolve( x, b )      Risolve il sistema lineare  $W(x) f = b$ ,
33 %                             dove  $W(x)$  e' la Vandermonde definita
34 %                             dagli elementi del vettore x.
35 %
36 f = b;
37 n = length( x )-1;
38 for k = 1:n
39     for i = n+1:-1:k+1
40         f(i) = f(i) - x(k)*f(i-1);
41     end
42 end
43 for k = n:-1:1
44     for i = k+1:n+1
45         f(i) = f(i)/( x(i) - x(i-k) );
46     end
47 for i = k:n
48     f(i) = f(i) - f(i+1);
49 end
50 end
51 return

```

Listing 23: LMF solver

We can write the following MATLAB function which explicitly calculates boundary locus values for a given LMF method:

```

1 function [q] = boundaryLocus(theta0,steps,method)
2     if method<0 || method > 2
3         disp('metodo non valido\n');
4         return;
5     end
6     theta=linspace(theta0,2*pi+theta0,100);
7     [ro,sigma]=lmf(method,steps);
8     q=zeros(1,100);
9     for j=1:100
10        q(j)=polyval(ro,exp(1i*theta(j)))/polyval(sigma,exp(1i*theta(j)));
11    end
12 end

```

Listing 24: Boundary Locus calculation

Consider now to execute the following script:

```

1 method=input('insert method to use\n');
2 if method<0 || method > 2
3     disp('invalid method');
4     return;
5 end
6 steps=input('insert max number of steps\n');
7 theta0=input('insert theta initial value\n');
8 hold all;
9 for j=1:steps
10    q=boundaryLocus(theta0,j,method);
11    plot(q,'DisplayName',[ 'number of steps = ' num2str(j)]);
12    if method==0—
13        strm="BDF";
14    elseif method==1
15        strm="Adams Moulton";
16        axis([-6 1 -5 5]);
17    else
18        strm="Adams Bashforth";
19    end
20    title(['Boundary Locus for LMF method ' strm]);
21 end
22 legend(gca,'show','Location','southeast');

```

Listing 25: Plot Boundary Locus Script

By setting 5 maximum steps and 6 as theta initial value, we obtain the results shown in figures 19,20 and 21.

Figure 19: BDF Boundary Locus

Figure 20: Adams Moulton Boundary Locus

Figure 21: Adams Bashforth Boundary Locus

7 Leslie Model

This model describes the demographic structure of a homogeneous population, structured in age classes.

Let L be the maximum reachable age in a population. We divide this temporal arc in intervals of size:

$$\tau = \frac{L}{m}$$

We denote by

$$x_i(k), \quad i = 1, \dots, m$$

The number of people aged between

$$[(i-1)\tau, i\tau], \quad i = 1, \dots, m-1$$

Where

$$0 < \beta_i \leq 1 \quad i = 1, \dots, m-1$$

Is the survival coefficient of class i at time τ .

We have:

$$\begin{cases} x_{i+1}(k+1) = \beta_i x_i(k) & i = 1, \dots, m-1 \\ x_1(k+1) = \sum_{i=1}^m \alpha_i x_i(k) & \text{are the new born} \end{cases}$$

Where $\alpha_i > 0$ are birth rate of respective age classes.

We obtain the following discrete dynamic system:

$$\mathbf{x}(k+1) \equiv \begin{bmatrix} x_1(k+1) \\ x_2(k+1) \\ \vdots \\ x_m(k+1) \end{bmatrix} = \begin{bmatrix} \alpha_1 & \dots & \alpha_{m-1} & \alpha_m \\ \beta_1 & & & \\ & \ddots & & \\ & & \beta_{m-1} & \end{bmatrix} \begin{bmatrix} x_1(k) \\ x_2(k) \\ \vdots \\ x_m(k) \end{bmatrix}$$

Consider the following MATLAB function:

```

1 function [nextgen] = leslie(alphai,betai,actgen)
2   m = length(alphai);
3   if m ~= length(betai)+1
4       error('beta i must be length as alpha i -1');
5   end
6   M = zeros(m,m);
7   for i=1:m
8       M(1,i)=alphai(i);
9   end
10  for i=2:m
11      for j=1:m
12          if(i-1 == j)
13              M(i,j) = betai(j);
14          end
15      end
16  end
17  nextgen = M*actgen;
18 end

```

Listing 26: Leslie model function

This function calculates next generation for each age class. We can call it iteratively for a fixed number of steps N to obtain a simulation model which describes the evolution of a population. For this purpose, we consider to use the following MATLAB function:

```

1 function [gens] = population(alphai,betai,startgen,steps)
2     gens=zeros(length(startgen),steps);
3     gens(:,1)=startgen;
4     for i=2:steps
5         gens(:,i)=leslie(alphai,betai,gens(:,i-1));
6     end
7 end

```

Listing 27: Leslie simulation function for a fixed number of steps

Consider now to execute this script:

```

1 %age classes      [Children]    [Young]      [Adult]      [Olds]
2 %birth rates     0.81844       0.070636    0.024407    0.003298
3 %survival        0.071936     0.189763    0.115040    0
4 %start gen       100          250          300         150
5 birth_rates=[0.81844,0.070636,0.024407,0.003298];
6 survival = [0.071936,0.189763,0.115040];
7 start_gen= [100,250,300,150];
8 n_steps = 5;
9 gens = population(birth_rates,survival,start_gen,n_steps);
10 hold on;
11 population_amounts = zeros(1,n_steps);
12 for i=1:n_steps
13     population_amounts(i)= (sum(gens(:,i)));
14     disp(['generation ', num2str(i) ':']);
15     disp(['[Children]          —————> ', num2str(gens(1,i)) ]);
16     disp(['[Youngs]           —————> ', num2str(gens(2,i)) ]);
17     disp(['[Adults]          —————> ', num2str(gens(3,i)) ]);
18     disp(['[Olds]            —————> ', num2str(gens(4,i)) ]);
19     disp(['[Total population] —————> ', num2str(population_amounts(i)) ]);
20 end
21 plot(population_amounts,'DisplayName','Amount of people');
22 legend(gca,'show','location','northeast');

```

Listing 28: Leslie script

We obtain the plot shown in figure 22. The console output produced by this script leads to the construction of the following dataset:

Classes	Generation 1	Generation 2	Generation 3	Generation 4	Generation 5
Children	100	107	90	74	61
Young people	250	7	8	6	5
Adults	300	47	1	2	1
Old men	150	34	5	0	0
Total	800	195	104	82	67

If we increase the number of generation as it reaches infinity, we obtain the plot shown in figure 23.

Figure 23: Extinction of the population

8 Arms Race model

We formulate a continuous time model which describes the level of two nation's arms. Let $x(t), y(t)$ be the nation's arms levels, we have:

$$x'(t) = -ax(t) + by(t) + \xi_0$$

$$y'(t) = cx(t) - dy(t) + \eta_0$$

Where all coefficients are positive:

- a, d are called fatigue coefficients
- b, c are called competition coefficients
- ξ_0, η_0 are called "base" levels, and they depend solely on the cultural connotations of the two nations in competition

In vectorial terms, we obtain the following positive dynamic system:

$$\begin{bmatrix} x \\ y \end{bmatrix}' = \begin{bmatrix} -a & b \\ c & -d \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} + \begin{bmatrix} \xi_0 \\ \eta_0 \end{bmatrix}$$

By applying Cramer rule, the equilibrium point is given by:

$$\bar{x} = \frac{d\xi_0 + b\eta_0}{ad - bc}$$

$$\bar{y} = \frac{c\xi_0 + a\eta_0}{ad - bc}$$

This point is asimptotically stable if and only if it has positive components, so if and only if

$$ad > bc$$

In other words, if the product of fatigue coefficients are greater than competition ones. Consider the following MATLAB function:

```

1 function [xsol,ysol,tsol] = arms(a,b,c,d,xi,eta,x0,y0,t0,tf,h)
2   xt = @(t,x,yt) -a*x+ b*yt + xi;
3   yt = @(t,y,xt) c*xt - d*y + eta;
4   [xsol,ysol,tsol] = expliciteuler(xt,yt,h,x0,y0,t0,tf);
5 end
6
7 function [xn,yn,tn] = expliciteuler(f,g,h,x0,y0,t0,tf)
8   N = 1+((tf-t0)/h);
9   tn = linspace(t0,tf,N);
10  xn = zeros(1,N);
11  yn = zeros(1,N);
12  xn(1) = x0;
13  yn(1) = y0;
14  for i=2:N
15     xn(i) = xn(i-1) + h*f(tn(i-1),xn(i-1),yn(i-1));
16     yn(i) = yn(i-1) + h*g(tn(i-1),yn(i-1),xn(i-1));
17  end
18 end

```

Listing 29: Arms race model

We notice that the solution is approximated using an explicit euler method, slightly modified in a way such that functions x, y (the known derivatives) can support to being evaluated considering each other, indeed they depend on each other since we are solving an ODEs system. Another parameter is added to the anonymous functions x, y :

$$x = \lambda t, x, y_t. -ax + by_t + \xi$$

$$y = \lambda t, y, x_t. cx_t - dy + \eta$$

Parameters y_t, x_t represent the approximation of each other solution at the time step t , and ξ, η are free variables given from the context Γ . Since we are evaluating the solution of the system using an explicit method, we calculate the next solution using explicitly the last we obtained, thus at each iteration we know x_t and y_t . Consider the following script:

```

1 a=0.9; b=2; c=1; d=2;
2 xi=1.6; eta = 1.4;
3 x0 = 5; y0 = 2.5;

```

Figure 24: Arms race model with $a=0.9, b=2, c=1, d=2$ for which is not verified $ad > bc$

```

4 [ySol , xSol , tsol]=arms(a , b , c , d , xi , eta , x0 , y0 , 0 , 15 , 0.01) ;
5 plot( tsol , ySol) ;
6 hold on ;
7 plot( tsol , xSol) ;
8 grid on ;
9 legend( 'ySol' , 'xSol' , 'Location' , 'best' )

```

Listing 30: Arms race model plot script

When executed, we obtain the results shown in figures 24 and 25.

9 Diabetes mellitus model

Diabetes mellitus is a pathology that manifests through a high concentration of glucose in the blood and urine.

When the regulatory mechanisms in a healthy person works properly, the insulin produced by the pancreas counteracts the level of glucose in the blood, but in a non-healthy person who has diabetes, these mechanisms does not work properly and the glucose remains too high; and this is a threat for the individual health.

Let $G(t), H(t)$ be respectively the concentrations of glucose and insuline, and call $\overline{G}, \overline{H}$ the optimal concentrations.

In general we can hypotize a relation between the variation of these two concentrations and their actual concentration, in fact:

$$G'(t) = F_g(G(t), H(t))$$

$$H'(t) = F_h(G(t), H(t))$$

When concentrations are at their optimal level, the regulation mechanism has no need to intervene, so the system is in equilibrium. We have:

$$F_g(\overline{G}, \overline{H}) = 0$$

$$F_h(\overline{G}, \overline{H}) = 0$$

For sake of simplicity, we ttrranslate $G(t), H(t)$ in order to have the optimal levels equals to 0. So we'll consider:

$$g(t) = G(t) - \overline{G}$$

$$h(t) = H(t) - \overline{H}$$

Adding a constant does not change derivatives. Supposing that F_h and F_g are Taylor-developable at second order, we obtain the following system:

$$g'(t) = -m_1g - m_2h + \gamma_g(g, h) \quad (*)$$

$$h'(t) = m_3g - m_4h + \gamma_h(g, h)$$

Where γ_g, γ_h are functions which represents higher order terms of the development.

We assume all $m_i > 0$.

We define:

$$M = \begin{bmatrix} -m_1 & -m_2 \\ m_3 & m_4 \end{bmatrix}$$

The eigenvalues of matrix M have negative real parts, so due to the Perron theorem, all the system admits origin as a solution asimptotically stable.

We can solve (*) to obtain an explicit form of $G(t)$ function, which describes the blood's glucose concentration with respect to the time.

$$g(t) = Ae^{-\alpha t} \cos(\omega t + \varphi)$$

$$G(t) = \bar{G} + Ae^{-\alpha t} \cos(\omega t + \varphi)$$

For diagnostic purposes, the quantity ω is the most useful parameter. In fact, if

$$T = \frac{2\pi}{\omega} > 3.5h$$

the patient is in a pathological state.

If the first measure of the glycemic level is performed after an enough long period of fasting, we can assume that this has reached the optimal equilibrium state.

Then if we give to the patient a quantity of glucose proportional to the body weight and making m measures at prefixed instants t_i , $i = 1, \dots, m$, we can obtain the remaining parameters with the least squares method.

In other words, we look for the minimum of the following function:

$$F(\alpha, \omega, A, \varphi) = \sum_{i=1}^m (G_i - \bar{G} - Ae^{-\alpha t} \cos(\omega t + \varphi))^2 \quad (**)$$

If we have approximated parameters, we can use the following MATLAB function:

```

1 function [G] = diab(opt,A,m1,m2,m3,m4,phi,maxt,measures)
2   abscissa = linspace(0,maxt,measures);
3   N=length(abscissa);
4   beta = sqrt(m1*m4+m2*m3);
5   alpha = (m1+m4)/2;
6   omega = sqrt(beta^2-alpha^2);
7   G=zeros(1,N);
8   for i=1:N
9     G(i)=opt+A*exp(-alpha*abscissa(i))*cos(omega*abscissa(i)+phi);
10  end
11 end

```

Listing 31: Diabetes Mellitus Function

Where opt is the optimal glycemic blood value, A, m_1, m_2, m_3, m_4 and ϕ are the model parameters, which must be approximated by solving (**), $maxt$ is the maximum time measured, and $measures$ is the number of measurements done in the interval $[0, maxt]$.

Executing the following script, we obtain the result shown in figure 26.

```
1 optimalg = diab(80,30,0.1,1.2,3.3,1.1,-20,10,1000);
2 badg = diab(140,30,0.1,2,0.125,0.1,-40,10,1000);
3 plot(optimalg, 'DisplayName', 'Normal glycemic level');
4 hold on;
5 grid on;
6 plot(badg, 'DisplayName', 'Pathologic glycemic level');
7 legend(gca, 'show', 'Location', 'best');
```
